Abstract

The rapid progress of computer science has been accompanied by a corresponding evolution of computation, from classical computation to quantum computation. As quantum computing is on its way to becoming an established discipline of computing science, much effort is being put into the development of new quantum algorithms. One of quantum algorithms is Grover's algorithm, which is used for searching an element in an unstructured list of \( N \) elements with quadratic speed-up over classical algorithms. In this work, Quantum Computer Language (QCL) is used to make a Grover's quantum search simulation in a classical computer document.

Keywords: Grover's Algorithm, Quantum Computer Language, Hadamard-Transform

1. Introduction

These instructions give you guidelines for preparing papers for Journal of Computer Science and Information – Universitas Indonesia. Use this document as a template if you are using Microsoft Word 6.0 or later. Otherwise, use this document as an instruction set. Instructions about final paper and figure submissions in this document are for Journal of Computer Science and Information – Universitas Indonesia; please use this document as a "template" to prepare your manuscript.

The rapid progress of computer science has been accompanied by a corresponding evolution of computation, from classical computation to quantum computation. In classical computation, computer memory made up of bits, where each bit represents either a one or a zero. In quantum computation, there are some quantum mechanical phenomena, such as superposition and entanglement, to perform operations on data. Instead of using bits, quantum computation uses qubits (quantum bits). A single qubit can represent a one, a zero, or both at the same time, which is called superposition. Because of this ability, quantum computation can perform many tasks simultaneously, faster than classical computing. There is also another phenomenon in quantum computation which is called entanglement. If two qubits get an outside force, then those qubits can be entangled condition. It means that, even the distance of both qubits is far, treating one of them will affect the other qubit too. For example, there are two entangled qubits, and one of them has spin up (we know it after done a measurement). Then without have to measure it, we can directly know that the other qubit has spin down. Because of this ability, communication in quantum computation can reach a very high speed because information can be transferred instantly, very fast like it overmatches the speed of light.
As quantum computing is on its way to becoming an established discipline of computing science, much effort is being put into the development of new quantum algorithms. One of quantum algorithms is Grover algorithm, which is used for searching an element in an unstructured list of N elements with quadratic speed-up over classical algorithms. Today, there are some quantum programming languages which can be used to simulate quantum mechanical and quantum algorithm without having a real quantum computer. In this work, Quantum Computer Language (QCL) will be used to make a Grover’s quantum search simulation in a classical computer.

This research is related to an invention of a quantum search algorithm by Lov K. Grover [1]. His invention presents an algorithm, which is known as Grover algorithm that is significantly faster than any classical algorithm can be. This quantum search algorithm can search for an element in an unsorted database containing N elements only in $O(\sqrt{N})$ steps, while in the models of classical computation, searching an unsorted database cannot be done in less than linear time (so merely searching through every item is optimal), which will be done in $O(N)$ steps. Also, this research will also try to simulate Grover algorithm in a classical computer using one of quantum programming languages, Quantum Computer Language (QCL) [2, 3].

In practice, this research can be used as the fastest known method or solution for searching an element in an unsorted database containing N elements. By using the method in this research, the searching process can speed-up quadratically over classical algorithms.

Considered points in this work are:
1. Is it possible to simulate Grover algorithm in a classical computer?
2. How many qubits and iterations the program needed to search an element?
3. How minimum and maximum the size of elements in the database that the program can hold?

The objective of this work is to to make a simulation of Grover algorithm using Quantum Computer Language (QCL), to know how many qubits and iterations needed for the searching process, and to know how minimum and maximum the size of elements in the database that can be hold by the program.

This paper concerns on simulating Grover algorithm in a classical computer using Quantum Computer Language (QCL). The program can search a desired element in an unsorted database of N elements.

This work begins with designing pseudo-code for Grover algorithm. Then, the design will be implemented by using Quantum Computer Language. After that, there will be several test to know how many qubits and iterations needed for the searching process, also to know how minimum and maximum the size of elements in the database that can be hold by the program.

2. Literature Review

Computer science has grown faster, made an evolution in computation. Research has already begun on what comes after our current computing revolution. This research has discovered the possibility for an entirely new type of computer, one that operates according to the laws of quantum physics - a quantum computer.

2.1. Way to Quantum Computation

Quantum computers were first proposed in the 1970s and 1980s by theorists such as Richard Feynman, Paul Benioff, and David Deutsch. At those times, many scientists doubted that they could ever be made practical. Richard Feynman was the first to suggest, in a talk in 1981, that quantum-mechanical systems might be more powerful than classical computers. In this lecture [4], reproduced in the International Journal of Theoretical Physics in 1982, Feynman asked what kind of computer could simulate physics and then argued that only a quantum computer could simulate quantum physics efficiently. He focused on quantum physics rather than classical physics. He said that nature isn’t classical, and if we want to make a simulation of nature, we’d better make it quantum mechanical, because it does not look so easy. Around the same time, in a paper titled "Quantum mechanical models of Turing machines that dissipate no energy" [5] and related articles, Paul Benioff demonstrated that quantum-mechanical systems could model Turing machines. In other words, he proved that quantum computation is at least as powerful as classical computation. But is quantum computation more powerful than classical computation? David Deutsch explored this question and more in his 1985 paper "Quantum theory, the Church-Turing principle and the universal quantum computer" [6]. First, he introduced quantum counterparts to both the Turing machine and the universal Turing machine. He then demonstrated that the universal quantum computer can do things that the universal Turing machine cannot, including generate genuinely random numbers, perform some parallel calculations in a single register, and perfectly simulate physical systems with finite dimensional state spaces. In 1989, in "Quantum
computational networks”[7], Deutsch described a
second model for quantum computation: quantum
circuits. He demonstrated that quantum gates can
be combined to achieve quantum computation in
the same way that Boolean gates can be combined
to achieve classical computation. He then showed
that quantum circuits can compute anything that
the universal quantum computer can compute, and
vice versa.

2.2. Superposition

Superposition is the fundamental law of
quantum mechanics. It describes the collection of all
possible states that an object can have. Superposition
means a system can be in two or more of its states simultaneously. For example
a single particle can be traveling along two different
paths at once.

The principle of superposition states that if
the world can be in any configuration, any
possible arrangement of particles or fields, and if
the world could also be in another configuration,
then the world can also be in a state which is a
superposition of the two, where the amount of
each configuration that is in the superposition is
specified by a complex number.

For example, if a particle can be in position
A and position B, it can also be in a state where it
is an amount "3i/5" in position A and an amount
"4/5" in position B. To write this, physicists
usually say:

$$|\psi\rangle = \frac{3}{5}|A\rangle + \frac{4}{5}|B\rangle$$

(1)

In the description, only the relative size of
the different components matter and their angle to
each other are on the complex plane. This is
usually stated by declaring that two states which
are a multiple of one another are the same as far
as the description of the situation is concerned.

$$|\psi\rangle \approx \alpha|\psi\rangle$$

(2)

The fundamental dynamical law of quantum
mechanics is that the evolution is linear, meaning
that if the state $A$ turns into $A'$ and $B$ turns into $B'$
after 10 seconds, then after 10 seconds the
superposition $\psi$ turns into a mixture of $A'$ and $B'$
with the same coefficients as $A'$ and $B'$.

Example: A particle can have any position,
so that there are different states which have any
value of the position $x$. These are written:

$$|x\rangle$$

The principle of superposition guarantees
that there are states which are arbitrary
superpositions of all the positions with complex
coefficients:

$$\sum_x \psi(x)|x\rangle$$

This sum is defined only if the index $x$ is
discrete. If the index is over $R$, then the sum is not
defined and is replaced by an integral instead. The
quantity $\psi(x)$ is called the wavefunction of the
particle.

If a particle can have some discrete
orientations of the spin, say the spin can be
aligned with the $z$-axis $|+\rangle$ or against it $|\rangle$, then
the particle can have any state of the form:

$$C_+|+\rangle + C_2|\rangle$$

If the particle has both position and spin, the
state is a superposition of all possibilities for both:

$$\sum_x \psi_+(x)|x, +\rangle + \psi_-(x)|x, -\rangle$$

The configuration space of a quantum
mechanical system cannot be worked out without
some physical knowledge. The input is usually the
allowed different classical configurations, but
without the duplication of including both position
and momentum.

A pair of particles can be in any combination
of pairs of positions. A state where one particle is
at position $x$ and the other is at position $y$ is
written $|x,y\rangle$. The most general state is a
superposition of the possibilities:

$$\sum_{i,j} A(x, y)|x, y\rangle$$

The description of the two particles is much
larger than the description of one particle; it is a
function in twice the number of dimensions. This
is also true in probability, when the statistics of
two random things are correlated. If two particles
are uncorrelated, the probability distribution for
their joint position $P(x, y)$ is a product of the
probability of finding one at one position and the
other at the other position:

$$P(x, y) = P_x(x)P_y(y)$$

(3)
In quantum mechanics, two particles can be in special states where the amplitudes of their position are uncorrelated. For quantum amplitudes, the word entanglement replaces the word correlation, but the analogy is exact. A disentangled wavefunction has the form:

$$\psi(x, y) = \psi_{1}(x)\psi_{2}(y)$$

while an entangled wavefunction does not have this form. Like correlation in probability, there are many more entangled states than disentangled ones. For instance, when two particles which start out with an equal amplitude to be anywhere in a box have a strong attraction and a way to dissipate energy, they can easily come together to make a bound state. The bound state still has an equal probability to be anywhere, so that each particle is equally likely to be everywhere, but the two particles will become entangled so that wherever one particle is, the other is too.

### 2.3. Entanglement

Quantum entanglement, also called the quantum non-local connection, is a property of a quantum mechanical state of a system of two or more objects in which the quantum states of the constituting objects are linked together so that one object can no longer be adequately described without full mention of its counterpart - even if the individual objects are spatially separated in a space-like manner. The property of entanglement was understood in the early days of quantum theory, although not by that name. Quantum entanglement is at the heart of the EPR paradox developed in 1935. This interconnection leads to non-classical correlations between observable physical properties of remote systems, often referred to as nonlocal correlations.

Quantum mechanics holds that observable, for example, spin are indeterminate until such time as some physical intervention is made to measure the observable of the object in question. In the singlet state of two spins it is equally likely that any given particle will be observed to be spin-up as that it will be spin-down. Measuring any number of particles will result in an unpredictable series of measures that will tend more and more closely to half up and half down. However, if this experiment is done with entangled particles the results are quite different. For example, when two members of an entangled pair are measured, their spin measurement results will be correlated. Two (out of infinitely many) possibilities are that the spins will be found to always have opposite spins (in the spin anti-correlated case), or that they will always have the same spin (in the spin correlated case). Measuring one member of the pair therefore tells you what spin the other member would have if it were also measured. The distance between the two particles is irrelevant.

Theories involving ‘hidden variables’ have been proposed in order to explain this result; these hidden variables account for the spin of each particle, and are determined when the entangled pair is created. It may appear then that the hidden variables must be in communication no matter how far apart the particles are that the hidden variable describing one particle must be able to change instantly when the other is measured. If the hidden variables stop interacting when they are far apart, the statistics of multiple measurements must obey an inequality (called Bell’s inequality), which is, however, violated - both by quantum mechanical theory and in experiments.

When pairs of particles are generated by the decay of other particles, naturally or through induced collision, these pairs may be termed “entangled”, in that such pairs often necessarily have linked and opposite qualities, i.e. of spin or charge. The assumption that measurement in effect "creates" the state of the measured quality goes back to the arguments of, among others: Schroedinger, and Einstein, Podolsky, and Rosen concerning Heisenberg’s uncertainty principle and its relation to observation (see also the Copenhagen interpretation). The analysis of entangled particles by means of Bell’s theorem, can lead to an impression of non-locality (that is, that there exists a connection between the members of such a pair that defies both classical and relativistic concepts of space and time). This is reasonable if it is assumed that each particle departs the scene of the pair’s creation in an ambiguous state (as per a possible interpretation of Heisenberg). In such a case, for a given measurement either outcome remains a possibility; only measurement itself would precipitate a distinct value. On the other hand, if each particle departs the scene of its "entangled creation" with properties that would unambiguously determine the value of the quality to be subsequently measured, then a postulated instantaneous transmission of information across space and time would not be required to account for the result. The Bohm interpretation postulates that a guide wave exists connecting what are perceived as individual particles such that the
supposed hidden variables are actually the particles themselves existing as functions of that wave.

Observation of wavefunction collapse can lead to the impression that measurements performed on one system instantaneously influence other systems entangled with the measured system, even when far apart. Yet another interpretation of this phenomenon is that quantum entanglement does not necessarily enable the transmission of classical information faster than the speed of light because a classical information channel is required to complete the process.

2.4. Hadamard Transform

The Hadamard transform (also known as the Walsh-Hadamard-transform, Hadamard-Rademacher-Walsh-transform, Walsh-transform, or Walsh-Fourier transform) is an example of a generalized class of Fourier transforms. It is named for the French mathematician Jacques Solomon Hadamard, the German-American mathematician Hans Adolph Rademacher, and the American mathematician Joseph Leonard Walsh. It performs an orthogonal, symmetric, involutional, linear operation on $2m$ real numbers (or complex numbers, although the Hadamard matrices themselves are purely real).

The Hadamard transform can be regarded as being built out of size-2 discrete Fourier transforms (DFTs), and is in fact equivalent to a multidimensional DFT of size $2 \times 2 \times \cdots \times 2 \times 2$. It decomposes an arbitrary input vector into a superposition of Walsh functions.

The Hadamard transform $H_m$ is a $2m \times 2m$ matrix, the Hadamard matrix (scaled by a normalization factor), that transforms $2m$ real numbers $x$ into $2m$ real numbers $x_k$. The Hadamard transform can be defined in two ways: recursively, or by using the binary (base-2) representation of the indices $n$ and $k$.

Recursively, we define the $1 \times 1$ Hadamard transform $H_0$ by the identity $H_0 = 1$, and then define $H_m$ for $m > 0$ by:

$$H_m = \frac{1}{\sqrt{2}} \begin{pmatrix} H_{m-1} & H_{m-1} \\ H_{m-1} & -H_{m-1} \end{pmatrix}$$

where $1/\sqrt{2}$ is a normalization that is sometimes omitted. Thus, other than this normalization factor, the Hadamard matrices are made up entirely of 1 and -1.

Equivalently, we can define the Hadamard matrix by its $(k, n)$-th entry by writing

$$k = k_{m-1}2^{m-1} + k_{m-2}2^{m-2} + \cdots + k_12 + k_0,$$

and

$$n = n_{m-1}2^{m-1} + n_{m-2}2^{m-2} + \cdots + n_12 + n_0,$$

where the $k_j$ and $n_j$ are the binary digits (0 or 1) of $n$ and $k$, respectively. In this case, we have:

$$(H_m)_{k,n} = \frac{1}{2^{m/2}} (-1)^{k \cdot n_j}.$$  (8)

This is exactly the multidimensional $2 \times 2 \times \cdots \times 2 \times 2$ DFT, normalized to be unitary, if the inputs and outputs are regarded as multidimensional arrays indexed by the $n_j$ and $k_j$, respectively. Some examples of the Hadamard matrices follow.

$$H_0 = +1$$  (9)

$$H_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$$  (10)

This $H_1$ is precisely the size-2 DFT. It can also be regarded as the Fourier transform on the two-element additive group of $Z(2)$.

$$H_2 = \frac{1}{2} \begin{pmatrix} 1 & 1 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \\ 1 & -1 & -1 \end{pmatrix}$$  (11)

$$H_3 = \frac{1}{2^{3/2}} \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & -1 & -1 & 1 & 1 & -1 \\ 1 & -1 & -1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 & -1 & -1 \\ 1 & 1 & -1 & -1 & -1 & 1 \end{pmatrix}$$  (12)

$$(H_n)_{i,j} = \frac{1}{2^{n/2}} (-1)^{i \cdot j}.$$  (13)

where $i \cdot j$ is the bitwise dot product of the binary representations of the numbers $i$ and $j$. For example,
Assuming with the above (ignoring the overall constant). Note that the first row, first column of the matrix is denoted by $H_{10}$. The rows of the Hadamard matrices are the Walsh functions.

In quantum information processing the Hadamard transformation, more often called Hadamard gate, is a one-qubit rotation, mapping the qubit-basis states $|0\rangle$ and $|1\rangle$ to two superposition states with equal weight of the computational basis states $|0\rangle$ and $|1\rangle$. Usually the phases are chosen so that we have

$$\frac{|0\rangle+|1\rangle}{\sqrt{2}} \langle 0| + \frac{|0\rangle-|1\rangle}{\sqrt{2}} \langle 1|$$

in Dirac notation. This corresponds to the transformation matrix

$$H_1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \tag{14}$$

in the $|0\rangle$ , $|1\rangle$ basis.

Many quantum algorithms use the Hadamard transform as an initial step, since it maps $n$ qubits initialized with $|0\rangle$ to a superposition of all $2^n$ orthogonal states in the $|0\rangle$ , $|1\rangle$ basis with equal weight. Hadamard gate operations:

$$H |1\rangle = \frac{1}{\sqrt{2}} |0\rangle - \frac{1}{\sqrt{2}} |1\rangle. \tag{15}$$

$$H |0\rangle = \frac{1}{\sqrt{2}} |0\rangle + \frac{1}{\sqrt{2}} |1\rangle. \tag{16}$$

$$H \left( \frac{1}{\sqrt{2}} |0\rangle - \frac{1}{\sqrt{2}} |1\rangle \right) = \frac{1}{2} (|0\rangle+|1\rangle) - \frac{1}{2} (|0\rangle-|1\rangle) = |0\rangle; \tag{17}$$

$$H \left( \frac{1}{\sqrt{2}} |0\rangle + \frac{1}{\sqrt{2}} |1\rangle \right) = \frac{1}{\sqrt{2}} \frac{1}{\sqrt{2}} (|0\rangle+|1\rangle) + \frac{1}{\sqrt{2}} \frac{1}{\sqrt{2}} (|0\rangle-|1\rangle) = |0\rangle. \tag{18}$$

2.5. Grover’s Quantum Search Algorithm

One of the most celebrated achievements of quantum computation is Lov Grover’s quantum search algorithm (known as Grover’s algorithm), which was invented in 1996. Grover’s algorithm is a quantum algorithm for searching an unsorted database with $N$ entries in $O(N^{1/2})$ time and using $O(\log N)$ storage space.

In models of classical computation, searching an unsorted database cannot be done in less than linear time (so merely searching through every item is optimal). Grover’s algorithm illustrates that in the quantum model searching can be done faster than this; in fact its time complexity $O(N^{1/2})$ is asymptotically the fastest possible for searching an unsorted database in the quantum model. It provides a quadratic speedup.

There are already related works about Grover algorithm, such as done by Matthew Whitehead, Ahmed Younes, and C. Lavor et.al., Matthew Whitehead’s paper [8] shows how Grover’s quantum search may be used to improve the effectiveness of traditional genetic search on a classical computer. He uses repeated applications of Grover’s Algorithm to get a variety of decent chromosomes that will then be used to form a starting population for classical genetic search. He also provides the pseudo code for the modified genetic search, which is a combination between Grover’s quantum search and standard genetic search. Another work related to Grover algorithm is done by Ahmed Younes. In his paper [9], he described the performance of Grover’s algorithm, and also wrote a review about Grover algorithm by means of a detailed geometrical interpretation and a worked out example. Some basic concepts of Quantum Mechanics and quantum circuits are also reviewed.

3. Design and Implementation

Many problems in classical computer science can be reformulated as searching a list for a unique element which matches some predefined condition. If no additional knowledge about the search-condition $C$ is available, the best classical algorithm is a brute-force search i.e. the elements are sequentially tested against $C$ and as soon as an element matches the condition, the algorithm terminates. For a list of $N$ elements, this requires an average of $N/2$ comparisons. By taking advantage of quantum parallelism and interference, Grover found a quantum algorithm [1] which can find the matching element in only $O(\sqrt{N})$ steps.

In this paper, Grover algorithm and its implementation will be explained process by process. The algorithm consists of two parts: (1)
3.1. **Input and Initialization**

3.1.1. **Input**

This simulation needs to know what number it should search, so user will be prompted to input a round number (integer). The implementation of this input process can be seen below.

```c
input "Enter an integer that will be find: ",bil;
```

In the code implementation above we can see that bil is a variable that is used to store the round number.

3.1.2. **Initialization**

Initialization is a process to initiate variables and qubit registers needed in the simulation. The most important variables that we have to initiate are the number of qubits and the number of iterations needed. Assume that the number of qubits is called sumqubit, and the number of iterations is called iteration.

To calculate the number of qubits needed, we can use this formula:

$\text{sumqubit} = \lceil \log(bil, 2) \rceil + 1$ \hspace{1cm} (19)

To calculate the number of iterations needed, we can use this formula:

$\text{iteration} = \lceil \pi/8 \times \sqrt{2^{\text{sumqubit}}} \rceil$ \hspace{1cm} (20)

Then, after the value of both sumqubit and iteration are known, another important step to do is to set up the registers for each qubits. Also, some variables need to be listed to for common process; looping, storing result, etc. The code implementation for initialization can be seen below.

```c
int sumqubit = floor(log(bil,2)) + 1;
int iteration = ceil(pi/8*sqrt(2^sumqubit));
int i;
qureg q[sumqubit];
qureg f[1];
print "Number of qubit are used: ",sumqubit;
print "Number of iteration are needed: ",iteration;
print "start searching process ...
```

3.1.3. **Main Loop**

Main loop is the main process to begin searching. The steps to do in the main loop are:

1. Reset all qubits to $|0\rangle$ and apply the Hadamard transform to each of them.
2. Repeat the following operation as much as the number of iterations needed (see the initialization part):
   - Rotate the marked state by a phase of $\pi$ radians ($\frac{\pi}{f}$). A query function needs to be applied. The query function is needed to flip the variable $f$ if $x$ (the qubits) is equal to 1111...
   - Apply a phase process between $\pi$ and $f$.
   - Undo the query function.
   - Apply a diffusion function. The process are apply Hadamard transform, invert $q$, then apply a phase process between $\pi$ and $q$ (rotate if $q$=1111..). After that, undo the invert process and undo Hadamard transform.
   - Do an oracle function by measure the quantum register that has been found, and then compare the result to the input.

These iterations must be repeated again if the measurement result does not match with the wanted number.

The code implementation of the main loop including the functions in it can be seen below.

```c
{ reset;
  H(q); 
  for i = 1 to iteration {
    print "Iteration ",i;
    query(q,f,bil);
    CPhase(pi,f);
    !query(q,f,bil);
    diffuse(q);
  }
  oracle(q,rmeasurement,bil);
  until rmeasurement==bil;
  reset;
}
```

3.1.4. **Query Procedure**

procedure query(qureg x,quvoid f,int bil) 
{
  int i;
  for i=0 to #x-1 {
    if not bit(bil,i) {
      Not(x[i]);
    }
  } 
  CNot{f,x};
  for i=0 to #x-1 {
    if not bit(bil,i) {
      Not(x[i]);
    }
  }
}

3.1.5. **Diffuse Procedure**

procedure diffuse(qureg q) 
{ 
  H(q);
  Not(q);
}
CPhase(\pi, q);
!Not(q);
!H(q);
}

3.1.6. Oracle Procedure

This procedure is for checking whether the measurement result is match with the wanted number or not. In general, the oracle function can be formulated as below.

\[ f(x) = \begin{cases} 1 & \text{if } x = x_0 \\ 0 & \text{if } x \neq x_0 \end{cases} \]

\( x \) is the indexes in the database, and \( x_0 \) is the wanted index. Back to the simulation, before we implement the oracle, we need to do a measurement to check if the number that been found is already matched with the wanted number. The code implementation can be seen below.

```c
procedure oracle(qureg q, int hasil-
measurement,bil)
{
    measure q,rmeasurement;
    if rmeasurement==bil {
        print "result of measurement:",
rmeasurement;
        print "has equaled with the
searched number...";
    } else {
        print "result of measurement:",
rmeasurement;
        print "not equaled with the
searched number...";
    }
}
```

4. Results and Discussion

The Grover’s quantum search simulation can be running from Linux’s terminal, by going to the directory where the file is put in then typing "qcl -i -b32 SimulasiGrover.qcl". This command will start QCL then run a file named SimulasiGrover.qcl, and providing all qubits that QCL has (32 qubits). To discuss the results of the program, Table I, containing ten outputs from Grover’s quantum search simulation program is provided.

In Table I, column "Input" is for the number that the user wants to find. Column "Qubits" is the total of qubits needed to search the number. Column "Iterations" is the total iterations needed to find one number to be measuring. Column "List of Measured Numbers" is the list of numbers that are found and get measured until the number is same to the input. Column "Total Iterations" is the total of iterations needed to find the correct number. The value of this column is the multiplication of the value in column "Iterations" and the amount of numbers in column "List of Measured Number.

</table>

From the table, we can see that the number of qubits and the number of iterations needed are depend on the value of the number that user wants to find. If the number is bigger, so will the qubits and the iterations be. Sometimes, the number that the program found is not matched with the input. If this condition is happen, the program will do the iterations again until the number is matched with the input. But even the program do the iterations more than one round, the total iterations is never exceed the value of the input. We can see this from the table in the column "Total Iterations". But this Grover’s quantum search simulation has a limitation; the maximum qubits that the program can use is only 32 qubits (QCL limitation). For the possible real implementation, Grover’s algorithm can be used for searching a record in database and improving the traditional genetic search.

5. Concluding Remarks

Using QCL, a Grover’s quantum search simulation has been made. It is performed without using a quantum computer, but using a classic computer. To search an element, the program needs to use qubit instead of bit. The number of qubits needed depend on the value of the number that we want to find. The bigger the value of the number, the bigger qubits needed. It goes the same with the number of iterations needed. The minimum value for the number is 1, and the maximum value is depending on the qubits needed. At this far, the program has been tested to search number till 9999. This Grover’s quantum search is just a simulation to simulate the
algorithm, not a real quantum searching program that can be implemented on the real database.

This Grover’s quantum search is just a simulation of quantum search in a classic computer. That is some possible works for the future related to Grover algorithm. Some of them is implementing Grover algorithm in a real database using quantum computer, but in this case, the database must be converted in to quantum states which is probably the most difficult thing to do. Another possible work is improving the traditional genetic search by combine it with Grover’s algorithm.

Appendix

Listing Program

```plaintext
procedure query(qureg x, quvoid f, int bil) {
    int i;
    for i=0 to $x$-1 {     // x -> NOT
        if not bit(bil,i) {
            Not(x[i]);
        }
        CNot(f,x);            // flip f
    }
    CPhase(pi,f);            // rotate |q>
    for i=0 to $x$-1 {     // x <- NOT
        if not bit(bil,i) {
            !Not(x[i]);
        }
    }
}

procedure diffusi(qureg q) {
    H(q);              // Hadamard
    Not(q);            // Inversi q
    CPhase(pi,q);      // Rotate
    !Not(q);           // undo inversi
    !H(q);             // undo
}

procedure algoritma(int bil) {
    int sumqubit = floor(log(bil,2))+1;
    // number of qubit
    int iteration = ceil(pi/8*sqrt (2^sumqubit));
    // number of iteration
    int rmeasurement, i;
    qureg q[sumqubit];
    qureg f[1];
    print "Number of qubit are used:" , sumqubit;
    print "Number of iteration are needed:" , iteration;
    print "Start searching process...";
    for i = 1 to iterasi {
        // main loop
        print "Iteration",i;
        query(q,f,bil);
        // count C(q)
        CPhase(p,q);
        // negation |n>
        !query(q,f,bil);
        // undo C(q)
        diffusi(q);
    }
    // oracle
    measure q,rmeasurement;
    // measurement
    if rmeasurement==bil {
